

being augmented by  $\sigma\sigma''$  and  $(p')^2$ , we obtain the transition energies 4.62, 2.14, and 0.64 eV for  $\text{CF}_2$ , FCH, and  $\text{CH}_2$  and the results labeled CI in Figures 9–11 and Tables I–III. While we are encouraged by the agreement with experiment, we consider it somewhat fortuitous since it is quite likely that the correlation energy loss upon dissolution of the  $\sigma^2$  lone pair is greater<sup>32</sup> than the 0.25 eV we find from the minimal CI.

**D. Singlet-Triplet Transition.** In going from the  $^3\text{B}_1$  state of  $\text{CF}_2$  or  $\text{CH}_2$  to the corresponding  $^1\text{B}_1$  state we neither disrupt any existing nor form any new electron pairs and we therefore expect the correlation energy in these two states to be comparable. Consequently, we anticipate that the energy difference  $^1\text{B}_1 - ^3\text{B}_1$  or  $^1\text{A}' - ^3\text{A}'$  should be adequately represented by the various CI functions we have described. To the extent that this is true we note that the reliability of our  $^1\text{A}_1 - ^3\text{B}_1$  or  $^1\text{A}' - ^3\text{A}'$  separations may be estimated by observing how well we account for the various singlet-singlet transitions. Since we do very well in estimating this transition in  $\text{CF}_2$  ( $^1\text{B}_1 \leftarrow ^1\text{A}_1$ ) and FCH ( $^1\text{A}'' \leftarrow ^1\text{A}'$ ) (see Table IV), we expect the singlet-triplet separations to be accurate, so in  $\text{CF}_2$  we predict that the  $^3\text{B}_1$  is 39 kcal above the  $^1\text{A}_1$  state, while in FCH the  $^1\text{A}'$  and  $^3\text{A}''$  are separated by a very small ( $\approx 0$  kcal) energy. Also, since our computed energy for the

(32) Indeed E. A. Scarzafava, Ph.D. Thesis, Indiana University, 1969, estimates the correlation energy in an oxygen lone pair in the water molecule as approximately 1 eV.

$\tilde{\text{A}}^1\text{B}_1 \leftarrow \tilde{\text{X}}^1\text{A}_1$  transition in  $\text{CH}_2$  is too low by 5 kcal we expect the  $^3\text{B}_1$  to be 19 kcal below the  $^1\text{A}_1$  state even though our raw data predict this separation to be 24 kcal.

Our estimate is in disagreement with recent experimental results<sup>33</sup> which indicate a separation of 1–2 kcal, and on the basis of the above arguments this would imply an error of 18 kcal in the  $^1\text{B}_1 - ^3\text{B}_1$  separation, which seems unreasonable. However, since this discrepancy must be resolved, we are undertaking a detailed study of the correlation energy contribution to the various states of  $\text{CH}_2$  and will report the results as soon as possible.<sup>34</sup>

**Acknowledgment.** The contour plots were constructed with routines written by Dr. Vincent Nicely, and it is a pleasure to acknowledge their use.

(34) NOTE ADDED IN PROOF. Recently, O'Neil, Schaefer, and Bender, manuscript in preparation, have used the iterative natural orbital technique [C. F. Bender and E. R. Davidson, *J. Phys. Chem.*, **70**, 2675 (1966)] to construct wave functions for various states of  $\text{CH}_2$ . Using Huzinaga's (9s5p/4s) basis [(S. Huzinaga, *J. Chem. Phys.*, **42**, 1293 (1965)] contracted to [4s2p/2s] as recommended by Dunning [T. H. Dunning, Jr., *J. Chem. Phys.*, **53**, 2823 (1970)], a 298 and a 408 configuration representation of the  $^1\text{A}_1$  and  $^3\text{B}_1$  states, respectively, were constructed as a function of geometry. Their result for the  $^3\text{B}_1 - ^1\text{A}_1$  splitting,  $E(^3\text{B}_1 (133.3^\circ)) - E(^1\text{A}_1 (104.4^\circ)) = -0.96 \text{ eV} (-22 \text{ kcal})$ , is in substantial agreement with ours but is still in conflict with the interpretation of the experimental data of ref 33. I thank Professor Schaefer for forwarding the results of his study before publication.

## Viscosity Dependence of Fluorescence Quantum Yields

S. Sharafy and K. A. Muszkat\*<sup>1</sup>

*Contribution from the Department of Chemistry,

and the Physikalisch-Chemisches Institut der Universität Basel,  
Basel, Switzerland. Received October 28, 1970*

**Abstract:** The normally nonfluorescent *cis*-stilbene and sterically hindered *trans*-stilbenes become strongly fluorescent in very viscous media. Thus a maximum fluorescence quantum yield ( $\phi_F$ ) of 0.75 is measured for *cis*-stilbene in a hydrocarbon glass. The fluorescence of these compounds is a steep function of the viscosity, due to a solvent free volume (and viscosity) dependent rate constant for the internal conversion ( $\text{S}_1 \rightarrow \text{S}_0$ ) process. This dependence is traced to the effect of enhanced solvent viscosity in reducing the probability and amplitude of the twisting and out-of-plane-bending modes about the central double bond. The theoretical dependence of  $\phi_F$  on viscosity is developed along the lines of the free volume theory of viscosity and is obeyed accurately by the experimental results. An uncoupling of fluorescence and intersystem crossing at high viscosities is observed for *trans-p*-bromostilbene and for *trans*-hexamethylstilbene. The photochemical significance of this uncoupling is examined.

The quantum yields of the *trans* to *cis* photoisomerization,  $\phi_t$ , of planar stilbenes were recently found to depend very strongly on the viscosity of the medium.<sup>2</sup> The effect was shown to be due to a solvent free volume dependent intramolecular rearrangement process subsequent to the  $\text{S}_1 \rightarrow \text{T}_2$  or  $\text{S}_1 \rightarrow \text{T}_1$  intersystem crossings,<sup>2–4</sup> and the theory<sup>2</sup> for a process of this type

was developed along the lines of the free volume theory of the viscosity of liquids.<sup>5</sup>

In the present paper we wish to describe the results of an investigation of the dependence of the fluorescence quantum yields  $\phi_F$  on the viscosity in a number of nonpolar aromatic compounds.<sup>6</sup> We have observed a

strong dependence of  $\phi_F$  on the viscosity only in stilbenes, and for these compounds we treat the effect in terms of the theory of free volume controlled mono-molecular processes. The study of viscosity dependent photochemical processes has important mechanistic implications if two concurrent processes show independent behavior. This is the case for fluorescence and trans to cis photoisomerization in several stilbenes, and the conclusions to be drawn from this research will be discussed.

### Experimental Section

Most of the experimental details are described in the previous publications.<sup>2,4,7</sup> 1,2-Diphenylcyclobutene was obtained from Dr. DeBoer.<sup>8</sup> A considerably purer grade of glycerol (Matheson Coleman and Bell, Spectroquality, anhydrous) was used in the present study. *cis*-Stilbene was purified by fractional distillation *in vacuo*. The purity of the compounds was checked by gas chromatography. The solutions in glycerol were prepared by a 100-fold dilution with glycerol of stock solutions in ethanol. Control experiments indicate that this amount of ethanol does not affect the viscosity nor the results to any significant extent. The solutions were degassed *in vacuo*. For this study we have used two fluorescence standards. *p*-Terphenyl,  $\phi_F = 0.93$ ,<sup>9</sup> was used for compounds with emission centered in the range 310 to 420 nm, and 9,10-diphenylanthracene,  $\phi_F = 1.00$ ,<sup>9</sup> was used for the 390–520-nm range. The quantum yields were corrected for the change of refractive index of the solution with the temperature. It was found in this study that too low  $\phi_F$  values were reported previously<sup>2,3</sup> for *trans*-stilbene in hydrocarbon glasses at 90°K, and in glycerol at and below room temperature. The differences were traced to the lack of correction for refractive index *vs.* temperature changes and to the relatively high internal light filtering by the previously used glycerol samples.

In most of the present experiments the viscosity of a given glass-forming solvent was changed by changing the temperature. The range of viscosity values required in the present study extends beyond the experimentally determined values for glycerol<sup>10</sup> and for the methylcyclohexane–methylcyclopentane (1:1) mixture,<sup>11</sup> MCH–MCP. These viscosity values ( $\eta$ ) were estimated by extrapolation

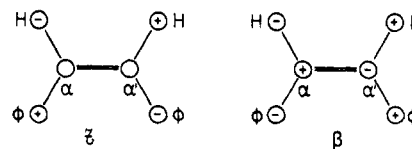

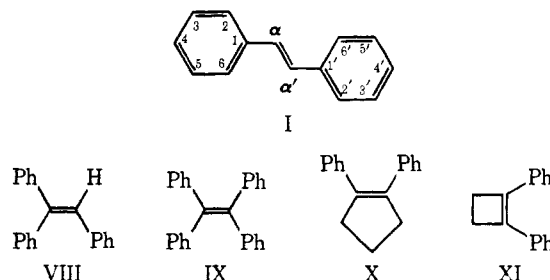

Figure 2. Schematic description of the twisting ( $\tau$ ) and out-of-plane bending ( $\beta$ ) vibration modes of stilbenes.

of the experimental values<sup>10,11</sup> using the empirical equation of Litovitz<sup>12</sup>

$$\log \eta = A + B/T^3 \quad (1)$$

which represents very accurately the experimental behavior for glycerol<sup>12</sup> and for MCH–MCP (Figure 1) for viscosities up to 10<sup>6</sup> cP.

In the present paper the solute molecules will be denoted as follows: I, *trans*-stilbene; II, 3,3',5,5'-*trans*-tetramethylstilbene; III, *cis*-stilbene; IV, *trans*- $\alpha$ -methylstilbene; V, *trans*- $\alpha,\alpha'$ -dimethylstilbene; V', *cis*- $\alpha,\alpha'$ -dimethylstilbene; VI, *trans*-2,4,6-trimethylstilbene; VII, *trans*-2,4,6,2',4',6'-hexamethylstilbene; VII', *cis* isomer of VII; VIII, triphenylethylene; IX, tetraphenylethylene; X, diphenylcyclopentene; XI, diphenylcyclobutene; and XII, *trans*-4-bromostilbene. Typical fluorescence and absorption spectra

of stilbenes (e.g., for I;<sup>13</sup> III, VIII, and IX;<sup>14</sup> VI and VII;<sup>4</sup> X;<sup>7,15</sup> and XI<sup>16</sup>) have been described previously. The emission of stilbenes is known to be due exclusively to fluorescence.<sup>14,15</sup>

### Results and Discussion

**Structural Studies.** We have previously described the difference in the  $\phi_F$  values at low viscosities between planar *trans*-stilbenes and the necessarily nonplanar *cis*-stilbenes and sterically hindered *trans* isomers.<sup>4</sup> The planar molecules are fluorescent at room temperature (or slightly below) while the nonplanar compounds are in most cases nonfluorescent down to *ca.* 120°K. We tend to attribute this difference to increased rates of intersystem crossing and of internal conversion in the nonplanar molecules. The role of planarity on fluorescence has been examined at length in other systems.<sup>17,18</sup>

An important aspect of the present work is the identification of the vibration modes in the first excited singlet states which are responsible for the low  $\phi_F$  values in the nonplanar stilbenes at low viscosities. It is further assumed that when these motions are absent altogether (*i.e.*, in rigid nonplanar molecules) high  $\phi_F$  values are observed even at very low viscosities. In flexible non-

and II in glycerol are higher than in MCH-MCP. The results for low-viscosity solvents indicate that fluorescence in this group is intrinsically dependent on temperature (*i.e.*, in addition to any dependence on viscosity). The temperature dependence of the fluorescence of unhindered stilbenes,<sup>2,4,13</sup> will be reexamined in the present study.

(b) **Sterically Hindered Compounds.** Figures 3a, 4a, and 4b show that III or *trans*-stilbenes substituted at any of the  $\alpha, \alpha'$ ; 2,6,2'; or 6' positions are completely nonfluorescent at low viscosities (*i.e.*, down to *ca.* 170°K in MCH-MCP). The fluorescence observed in glycerol solutions of these compounds is thus due entirely to enhanced viscosity. An obvious problem that arises in the present context is whether the high  $\phi_F$  values in MCH-MCP are due to the low temperatures, to the high viscosities prevailing at these temperatures, or to both factors combined. The solution to this problem is suggested by the results of a comparative study of the fluorescence of III in two alcoholic solvents of different viscosities (Figure 5). Ethanol + 6.6% water<sup>10</sup> (E) was chosen as the fluid solvent and *n*-propyl alcohol<sup>10,24</sup> (P) as the viscous solvent. These results indicate that for any given temperature  $\phi_F$  is larger in the more viscous solvent. Thus at 123, 113, and 103°K the ratios  $\phi_F^P/\phi_F^E$  are equal respectively to 3.9, 2.7, and 2. Very similar results were obtained when comparing solutions of *cis*-stilbene in 3-methylpentane (3-MP) and in a mixture of 3-MP and MCH (1:20). Thus  $\phi_F = 0.40$  in 3-MP at 91°K and in MCH-3-MP at 102°K. The viscosity of these two solvent systems at the above temperatures is about  $10^7$ – $10^8$  cP.<sup>24</sup> These results indicate that high viscosity is the most important factor over this temperature range. However, some temperature dependence is also evident. Obviously, this reasoning is based on the assumption that, apart from different viscosities, these two solvent pairs would show similar specific effects, if any, due to their chemical similarity.

The two *cis* isomers of the hindered compounds V and VII were also studied. Their fluorescence spectra are

(24) A. C. Ling and J. E. Willard, *J. Phys. Chem.*, **72**, 1918, 3349 (1968).

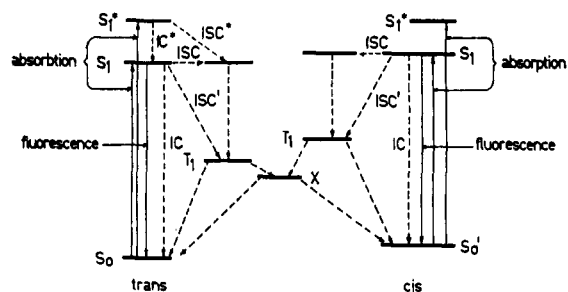

Figure 6. Jablonski-type scheme for the stilbene system.

red shifted in comparison with those of the *trans* isomers, and the quantum yields are very low, so that emission is discernible only at very low temperatures and high viscosities.

**Analysis of the Temperature Dependent Fluorescence in Planar *trans*-Stilbenes.** The experimental data on which is based the schematic description (Figure 6) of the different processes in the stilbene system have been described previously.<sup>2-4</sup> Further information about two radiationless processes of the singlet excited *trans* form is made available by the following analysis of the temperature dependence of  $\phi_F$  (in I and II) at low viscosities in MCH-MCP.

We assume that at low viscosities the temperature dependent behavior of  $\phi_F$  is due to the presence of the intersystem crossing process  $S_1 \rightarrow T_2$  (ISC) which requires an activation energy ( $E_a$ ) of a few kilocalories per mole. In the previous study a value of  $E_a = 1$ –4 kcal/mol was obtained from the temperature dependence of  $\phi_t$ .<sup>4</sup> The radiationless processes which compete with fluorescence (F) are IC, an internal conversion process ( $S_1 \rightarrow S_0$ ), and ISC and ISC',  $S_1 \rightarrow T_2$  and  $S_1 \rightarrow T_1$  intersystem crossings. Evidence for the existence of an intersystem crossing process which can populate the triplet manifold at 77°K was presented by Herkstroeter and McClure.<sup>25</sup> On the basis of the enhancement of the temperature independent intersystem crossing by an *n*-butyl bromide solvent<sup>3</sup> we now identify the process reported by Herkstroeter and McClure<sup>25</sup> as the temperature independent  $S_1 \rightarrow T_1$  process (ISC'). Evidence for a slightly temperature dependent IC ( $S_1 \rightarrow S_0$ ) is provided by the temperature dependent behavior of  $\phi_F$  in XII, where ISC is temperature independent. This process is therefore assumed by analogy for I and II. The  $\phi$  values of the above mentioned processes add up to unity.

$$\phi_{ISC'} + \phi_{ISC} + \phi_{IC} + \phi_F = 1 \quad (2)$$

We denote the maximal  $\phi_F$  at 77° as  $\phi_F^0$ . At this temperature  $\phi_{ISC} = 0$  and we further assume that  $\phi_{IC} = 0$ . Therefore we obtain at 77°

$$\phi_{ISC'} + \phi_F^0 = 1 \quad (3a)$$

and for any other temperature

$$\phi_{ISC} + \phi_{IC} + \phi_F = \phi_F^0 \quad (3b)$$

and

$$\phi_{ISC} + \phi_{IC} = \phi_F^0 - \phi_F \quad (3c)$$

By expressing the quantum yields as ratios of rate

(25) W. G. Herkstroeter and D. S. McClure, *J. Amer. Chem. Soc.*, **90**, 4522 (1968).

constants  $k$  we obtain that

$$\phi_F/(\phi_F^0 - \phi_F) = k_F/(k_{ISC} + k_{IC}) \quad (4)$$

We expect a range of temperatures for which  $k_{ISC} \gg k_{IC}$ . Therefore at these temperatures

$$\phi_F/(\phi_F^0 - \phi_F) \approx k_F/k_{ISC}^0 e^{-E_a/RT} \quad (5)$$

This is indeed the situation (Figure 7) at  $T > 200^\circ\text{K}$ . At lower temperatures the function  $\phi_F/(\phi_F^0 - \phi_F)$  changes less, as then  $k_{IC} \approx k_{ISC}$  or even  $k_{IC} > k_{ISC}$ . This is observed at  $T < 200^\circ\text{K}$ . The activation energy values for ISC (in the linear part of Figure 7) are 4.1 kcal/mol for I (cf. with  $E_a = 3$  kcal/mol from the temperature dependence of  $\phi_t$ ) and 3.8 kcal/mol for II.

**Analysis of the Viscosity Dependence of  $\phi_F$ .** We limit our treatment to the *cis*-stilbenes and the sterically hindered *trans*-stilbenes. These molecules have nonplanar ground states,<sup>23</sup> and intersystem crossing is independent of the viscosity and of the temperature. This is inferred from the behavior of  $\phi_t$  (for the *trans* isomers) and of  $\phi_c$  (for the *cis* isomers).<sup>2-4</sup> As in these compounds  $\phi_{ISC}$  is constant but  $\phi_F$  is not, we conclude that at high viscosities intersystem crossing (ISC\*) proceeds from a *higher energy singlet state* ( $S_1^*$ , cf. Figure 6). This state is converted into the  $S_1$  state by the internal conversion process IC\*. Stegemeyer has recently reported that high-viscosity solvents freeze down the molecular relaxation processes in III, VIII, IX, and in similar compounds.<sup>14</sup> Therefore, final states having geometries similar to that of the initial states (Franck-Condon states) are obtained either on emission or on absorption in high-viscosity solvents. These observations lead us to conclude that the  $S_1^*$  state is a Franck-Condon state with a nuclear configuration similar to that of the ground state. From these considerations we conclude that at any temperature and viscosity

$$\phi_{IC} + \phi_{ISC^*} + \phi_F = 1 \quad (6)$$

For any solvent the limiting fluorescence quantum yield,  $\phi_F^0$ , is achieved at the highest viscosities. We assume that then  $\phi_{IC} \rightarrow 0$ . Then

$$\phi_{IC} = \phi_F^0 - \phi_F \quad (7)$$

and

$$\phi_F/(\phi_F^0 - \phi_F) = \phi_F/\phi_{IC} = k_F/k_{IC} \quad (8)$$

We limit our treatment to cases where the fluorescence is determined by the viscosity. IC is the process whose rate constant  $k_{IC}$  is viscosity dependent. According to a previous publication<sup>2</sup> the dependence of  $k_{IC}$  on the mean free volume of the solvent,  $V_f$ , is given by

$$k_{IC} = k_{IC}^0 e^{-aV_0/V_f} \quad (9)$$

In eq 9  $k_{IC}^0$  is the free volume independent rate constant,  $V_0$  is the critical free volume for a motion of the solvent, and  $a$  is the fraction of  $V_0$  required for a motion of the solute. By adopting eq 9 for the present case we assume that a molecular vibration (e.g.,  $\tau$  or  $\beta$ ) can be treated much the same way as a molecular geometry change such as the *trans*-to-*cis* isomerization around a double bond.<sup>2</sup> The viscosity  $\eta$  is given by<sup>24a</sup>

$$\eta = \eta_0 e^{V_0/V_f} \quad (10)$$

Thus  $k_{IC}$  may be expressed in terms of the viscosity as

$$k_{IC} = k_{IC}^0 (\eta_0/\eta)^a \quad (11)$$

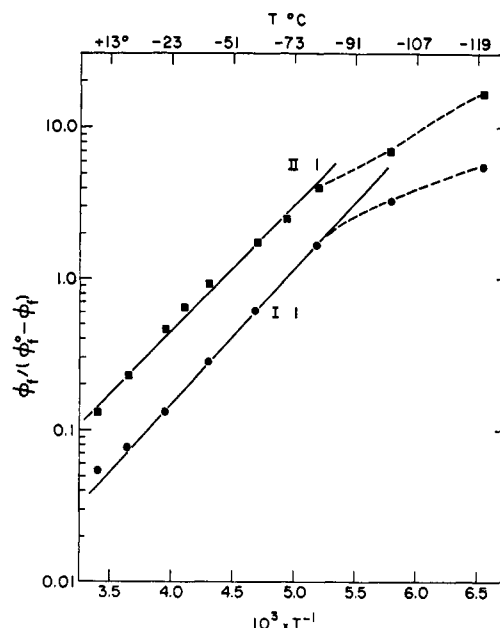

Figure 7. Plot of  $\phi_F/(\phi_F^0 - \phi_F)$  vs.  $1/T$  for *trans*-stilbene and *trans*-tetramethylstilbene (MCH-IH solutions).

Substitution for  $k_{IC}$  in eq 8 results in

$$\phi_F/(\phi_F^0 - \phi_F) = k_F/[k_{IC}^0 (\eta_0/\eta)^a] \quad (12)$$

The absorption spectra of the present compounds are independent of the viscosity. Thus  $k_F$  as well as  $k_F/(k_{IC}^0 \eta_0^a)$  are constant.  $k_F/(k_{IC}^0 \eta_0^a)$  will be denoted by  $A$ . Our final expression is then

$$\phi_F/(\phi_F^0 - \phi_F) = A/\eta^a \quad (12a)$$

Figures 8, 9, and 10 show the linear dependence of  $\log [\phi_F/(\phi_F^0 - \phi_F)]$  on  $\log \eta$  for III, IV, V, VI, VIII, IX, and X, as required by eq 12a. The slope of the curves,  $a$ , is larger for MCH-MCP than for glycerol. Thus for IX  $a$  is 1 in MCH-MCP but 0.2 in glycerol.  $a$  is in general a function both of the solvent and of the solute.

**Correlation between the Theory of Radiationless Transitions and the Viscosity Dependence of  $\phi_F$ .** We have shown in the previous sections that the molecular motions which have a direct influence on  $\phi_F$  are the twisting ( $\tau$ ) and the out-of-plane bending ( $\beta$ ) motions of the  $\alpha$ - $\alpha'$  double bond, in the excited state. The process whose rate constant depends on the viscosity (and on  $\tau$  and  $\beta$ ) was furthermore identified as the IC radiationless transition. In the present section we wish to examine the reasons for the strong effect of these vibrations on the rate constant of the IC transition.

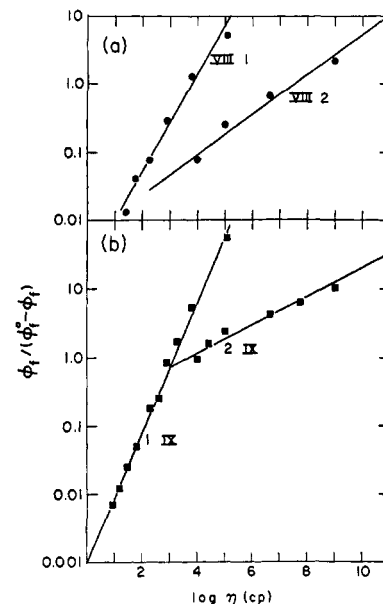

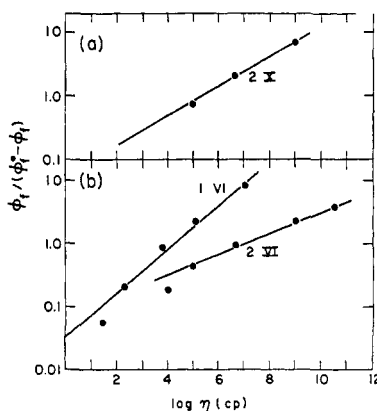

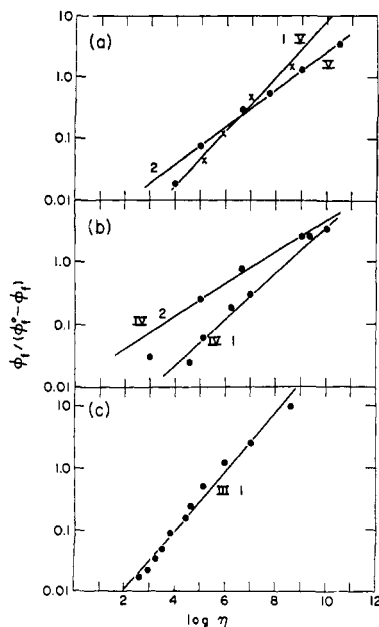

Of the many theories of radiationless transitions,<sup>26</sup> we chose for the present discussion the well-known formulation of Robinson and Frosch.<sup>27a</sup> According to this theory, the rate constant  $k$  for a radiationless transition ( $k_{IC}$  in the present case) is given by

$$k = (2\pi\beta_{el}^2/\alpha\hbar) \sum_n \langle \phi_n''/\phi_0' \rangle^2 \quad (13)$$

In this equation the summation represents the overall

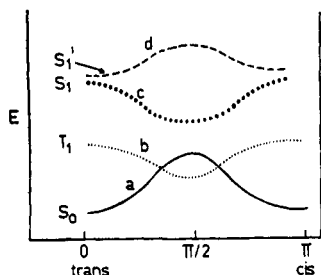

Figure 11. Schematic energy profiles for the twisting mode of stilbene. Curve d refers to a molar volume equal to that of the trans form.

vibrational overlap factor (Franck-Condon factor),  $\beta_{ei}$  is the matrix element of the electronic perturbation Hamiltonian  $H'$  between the final and initial wave functions, and  $\alpha$  is an inverse measure of the density of final states.

In the present discussion we shall be mainly concerned with the Franck-Condon (FC) factor of eq 13. This factor accounts for overlap of the lowest vibrational wave function of the higher electronic state (designated by a single prime),  $\phi_0'$ , with all the  $n$  different wave functions of the lower electronic state (designated by a double prime),  $\phi_n''$ .

Siebrand and Williams have recently investigated several of the factors which strongly increase the magnitude of FC factors for the  $S_1 \rightarrow S_0$  internal conversion.<sup>27b</sup> Among these factors are included the anharmonicity of the excited vibrations in the lower electronic state, the extent of change in the frequencies of the excited modes between the two states (distortions), and the extent of change in the normal coordinates proper to the excited normal modes (displacements).<sup>27b</sup> Low-frequency modes are expected to be particularly effective.<sup>27b</sup> All these requirements are obviously fulfilled by the  $\tau$  mode<sup>28</sup> and probably by the out-of-

plane-bending modes. However, this approach is unable to explain why modes  $\tau$  and  $\beta$  are of particular importance for the nonplanar molecules. It seems that for these other factors have also to be considered.

The experimental data of Auwers<sup>29</sup> on the molar volumes of sterically nonhindered (planar) and sterically hindered (nonplanar) isomers in solution point toward the general trend that planar molecules have smaller molar volumes than nonplanar molecules. We have therefore attributed the difference in the viscosity dependence of the quantum yields of geometrical photoisomerization between planar *trans*-stilbenes and the nonplanar *cis*- or *trans*-stilbenes to a difference in the molar volumes.<sup>2</sup>

According to this approach<sup>2</sup> the combined molecular volume of the solute and the mean free volume of the solvent are sufficient at all viscosities for the rotation about the central double bond in the nonplanar compounds. However, in the planar compounds this motion mode is probable only at low viscosities (*i.e.*, at high values of the solvent mean free volume). Thus at intermediate viscosities the probability of the twisting motion in a triplet state and therefore the photoisomerization quantum yield should show a dependence on the viscosity.

This same approach provides an immediate explanation of the present experimental results. In the previous sections we have seen that the motions involving the double bond ( $\tau$  and the  $\beta$ 's) are closely related to the magnitude of  $\phi_{FC}$  and to its dependence on the viscosity. We therefore wish to suggest that an important path for internal conversion in stilbenes is through tunneling of molecules twisted by  $90^\circ$  about the central double bond in  $S_1$  (Figure 11) to the perpendicular ground state. Figure 11 gives a qualitative description of the energy profiles of several electronic states important for the present context as a function of the angle of twist of the central double bond.<sup>30,31</sup> The lowest energy

gap  $S_1-S_0$  is between the perpendicular forms, and a radiationless transition  $S_1 \rightarrow S_0$  would be the most probable for this geometry. Curve c describes the energy of the  $S_1$  state at low viscosities. However, at high viscosities, depending on the solute and on the viscosity, a potential barrier of varying height which is required for a free volume limited motion will be superimposed on the potential curve of the  $S_1$  state of the isolated molecule (curve d). Therefore, planar *trans*-stilbenes which have low molar volumes will experience high viscosity dependent barriers to the  $\tau$  motion and will show a decrease of  $\phi_{IC}$  even at relatively low viscosities (Figure 3b). The nonplanar stilbenes which have higher molar volumes will show a decrease of  $\phi_{IC}$  only at much higher viscosities because they experience much lower free volume dependent barriers to rotations.

The present approach can also be applied to another chapter of the photochemistry of stilbene. Herkstroeter and McClure have observed that the lifetime of the triplet state of *trans*-stilbene is very strongly dependent on viscosity.<sup>25</sup> On the other hand, it is considerably increased by deuteration, but only at the  $\alpha$  and  $\alpha'$  positions (I).<sup>32</sup> These two observations can easily be correlated by assuming that a preferred path for the radiationless transition  $T_1 \rightarrow S_0$  (trans) which determines the lifetime of the triplet also involves a twisted or bent upper state. This state is converted to the isoenergetic lower state excited with one or several of the out-of-plane vibrations involving the double bond. These correspond respectively to the modes  $\nu_6$  ( $a_u$ ),  $\nu_7$  ( $a_u$ ), and  $\nu_8$  ( $b_g$ ) of  $\text{CHBr}=\text{CHBr}$ .<sup>19</sup> The transition  $T_1 \rightarrow S_0$  is, however, not a simple surface crossing but also requires some quantum mechanical tunneling. The frequencies of the out-of-plane bending vibrations  $a_u$  and  $b_g$  are probably strongly decreased by deuteration at  $\alpha$  and  $\alpha'$  (cf. the effect in  $\text{CHBr}=\text{CHBr}$ ),<sup>19</sup> while in the V state of ethylene deuteration is known to reduce considerably the frequency of the double bond twisting mode.<sup>33</sup> Energy profiles qualitatively similar to that for the twisting deformation (Figure 11) are also expected for the out-of-plane-bending modes.

The two effects on the lifetime of the triplet state of stilbene—that of viscosity and that of deuteration at the  $\alpha$  and  $\alpha'$  positions—are thus ascribed to the participation of the twisting and of the out-of-plane-bending modes in the radiationless  $T_1 \rightarrow S_0$  transition.

**Conclusion about the Mechanism of the Direct Cis-Trans Photoisomerization of Stilbenes.** The involvement of triplet levels in the direct photoisomerization of stilbenes has been a subject of controversy.<sup>2-4, 13, 22, 25, 34</sup> Mainly on the basis of quenching experiments of the sensitized and of the direct photoisomerization of stilbene, Saltiel, *et al.*, infer<sup>34</sup> that the unsensitized photoisomerization proceeds in an excited singlet level. However, studies of triplet sensitization<sup>13, 35</sup> and of the effects of internal and external heavy-atom enhancement<sup>2-4, 36</sup> on  $S_1 \rightarrow T_1$  and on  $S_0 \rightarrow T_1$  indicate that a triplet level is involved which may be directly observed by triplet-triplet absorption in flash photolysis.<sup>25</sup> The present investigation supports this last conclusion: the effects of high viscosity on  $\phi_F$  and on  $\phi_t$  values in VI and XII show that there is complete uncoupling of fluorescence and trans-to-cis photoisomerization in both VII and XII,<sup>37</sup> as well as in III, IV, V, and VI. Thus in VI  $\phi_t$  is independent both of temperature and of viscosity<sup>2, 4</sup> while  $\phi_F$  is strongly dependent on the viscosity and to a lesser degree on the temperature (Figure 3). In XII in glycerol solutions at  $-80^\circ$   $\phi_t$  is decreased to almost zero while  $\phi_F$  is approximately equal to its value at this temperature in the fluid MCH-MCP (cf. Figure 3).

(37) The present  $\phi_F$  values for *trans*-stilbene (I) show that here no experimental proof is available of uncoupling of fluorescence and of photoisomerization at high viscosities. At high viscosities, in glycerol solutions,  $\phi_t$  drops,<sup>2</sup> while  $\phi_F$  increases (see Figure 3), implying a viscosity dependent ISC process. An uncoupling of fluorescence and trans-to-cis photoisomerization at high viscosities<sup>2, 3</sup> was deduced erroneously for I from the previous set of  $\phi_F$  values.<sup>2, 3</sup> For I these are superseded by the present measurements (cf. Experimental Section).
